PACS `47.20.-k` – Flow instabilities
PACS `47.15.Fe` – Stability of laminar flows
PACS `47.27.nd` – Channel flow

Abstract. - Wall slip and wall divergence are known to have large and opposing effects on the stability of flow in a two-dimensional channel. While divergence hugely destabilises, slip dramatically stabilizes the linear mode. In a non-parallel stability analysis, we study a combination of these two effects, since both will coexist in small-scale flows with wall roughness. Our main results are (i) that the stabilising effect of slip is reversed at higher angles of divergence, (ii) transient growth of disturbances is unaffected by either wall-divergence, or by slip at any divergence. Moreover, at the Reynolds numbers relevant here, transient growth is too low to be a significant player in transition to turbulence, which is more likely to be driven by linear instability.

Introduction. – The laminar flow through a two-dimensional channel is linearly stable up to a Reynolds number of 5772, based on the channel half-width and the centreline velocity. Since the flow usually goes to turbulence at a much lower Reynolds number (between 1000 and 2000), the mechanisms leading to turbulence are accepted to be either directly nonlinear, or triggered initially by transient algebraic growth due to the superposition of linearly decaying waves. In the latter case, nonlinearities are said to take over once transient growth increases disturbance amplitudes to significant levels.

In this paper we investigate the combination of two large and opposing contributors to stability; channel divergence and velocity slip. We study both exponential and transient growth of instabilities. Our motivation is that in small-scale flows, wall-roughness can create local divergence and convergence of the flow, and slip can be significant, especially if the walls are hydrophobic, so the two effects are likely to act simultaneously. It was noted decades ago [1,2] that a small divergence of the wall can cause the critical Reynolds number for linear instability to plummet by two orders of magnitude. The transient growth of disturbances in this flow has not been investigated before, to our knowledge. The instabiliy of channel flow in the presence of velocity slip at the wall is receiving attention recently ([3,4] and references therein). The consensus for a plane channel is that wall slip hugely stabilizes the linear mode, but does not affect transient growth of instabilities much [5–7].

Under no-slip at the wall, our non-parallel linear stability analysis confirms the result obtained by [1] under the parallel flow assumption, that with increase in divergence, the critical Reynolds numbers falls sharply. There is a small quantitative change in the result due to nonparallel effects. On the other hand, we show that for small levels of wall divergence, transient growth of disturbances is unaffected by wall divergence. At the relevant Reynolds numbers, the magnitude of maximum of transient growth is small. Slip at the walls does not in this case have the "obvious" effect of huge stabilisation. In fact, wall slip can further destabilise the flow, although slightly.

At low Knudsen numbers, we take the Navier-Stokes equations to be valid in conjunction with the slip boundary condition of Maxwell [8],

$$U \pm Kn\frac{\mathrm{d}U}{\mathrm{d}y} = 0, \quad \text{at} \quad y = \pm 1. \tag{1}$$

This model is correct to $O(1)$ in the Knudsen number, Kn, expressed here as the ratio of slip length (l_s) to the local half-width $H(x)$ of the channel. The coordinates along, and normal to, the channel centreline are denoted as x and y respectively. All quantities are non-dimensionalised using $H(x)$ and the centreline velocity $U_c(x)$. In particular,

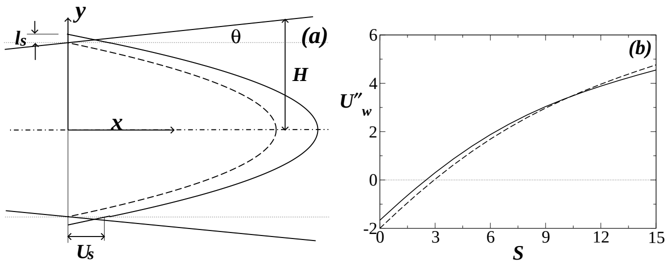

Fig. 1: (a) A schematic diagram showing the coordinate system, slip length and slip velocity. (b) Variation of U'' at the wall for different S (solid line: $Kn = 0.1$ and dashed line: $Kn = 0$).

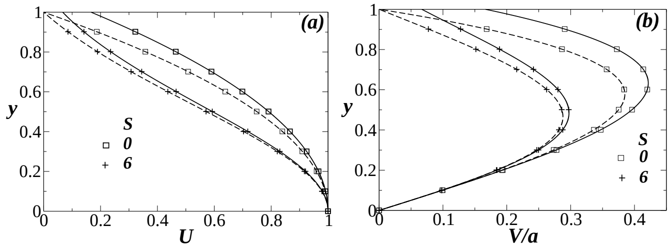

Fig. 2: (a) Streamwise, and (b) normal, components of the velocity at various values of the divergence parameter S. Solid line: $Kn = 0.1$, dashed line: no slip. The U and V are symmetric and anti-symmetric about the channel centreline ($y = 0$) respectively.

the relationship $\mathrm{d}x_d = H\mathrm{d}x$ is used later, where the subscript d represents a dimensional quantity. The Maxwell slip model breaks down around $Kn = 0.15$ [9], so we, like others [5–7, 10] who use this model, restrict ourselves to values below this. The slip length and slip velocity (U_s) are shown schematically in figure 1(a).

Incidentally the work of Lauga & Cossu [5] set to rest a recent controversy over the effect of slip on the stability of channel flow. Chu [10–12] had found a large destabilisation due to slip, in contrast to the earlier prediction of Gersting [13] of a huge stabilisation. The conclusions of [13] are confirmed by [5], who showed that there was a lapse in the application of the slip boundary condition in the work of Chu. There remains a small discrepancy in the effect of slip on transient growth, between the results of [5] and [6]. Both agree that the effect of slip is small, but the direction of the effect is stabilising in [6] and destabilising in the other. We have checked that this discrepancy arises from a difference in the definition of Reynolds number, since the velocity scale (from their respective analytical expressions) used by [6] decreases with increasing slip while that of [5] goes up with slip. In the present paper we avoid this ambiguity by scaling with the centreline velocity, obtained numerically, as explained in the next section. For the sake of validating our results, when we employ the respective definitions of [5] and [6], our calculations for a plane channel agree very well with each.

For a divergent channel, we use the Jeffery-Hamel mean flow profiles, described in the next section, followed in subsequent sections by the linear stability and computations of transient disturbance growth.

The basic flow. – At low angles of divergence, the incompressible laminar flow in a wedge-shaped channel is given by the Jeffery-Hamel equation (see e.g. [1]):

$$U''' + 2SUU' = 0, \tag{2}$$

which is valid for flows with slip boundary conditions as well. All effects up to the first order in the divergence have been retained in the Navier-Stokes equations, and similarity has been assumed. The primes denote derivative with respect to y. The only parameter is the product $S \equiv aRe$, of the slope a of the wall and the Reynolds number Re. (Some of the results below are presented in terms of the angle of divergence $\theta = \tan^{-1} a$). From global continuity we see that $Re \equiv H(x)U_c(x)/\nu$ is a constant for a given flow, ν being the kinematic viscosity. The normal velocity

$$V = ayU \tag{3}$$

from continuity. Note that V, being normal to the centreline, is not zero at the wall when there is a non-zero slip (U_s). Equation (3) with the boundary conditions given by equation (1) at the wall, and $U = 1$, $U' = 0$ at the centerline, is solved by a fourth order Runge-Kutta method. Thus for different Knudsen number the profile is computed numerically. The effect of slip at different S on the streamwise and normal components of the velocity is shown in figures 2(a) and (b) respectively.

Ever since Rayleigh [14] proved that a point of inflexion in the velocity profile is a necessary condition for inviscid instability, the second derivative U'' has been known to be a sensitive indicator of linear instability, especially when it goes through a zero somewhere in the flow. In a divergent channel, U'' at the centreline remains negative, and for small divergences, is close to the value in a plane channel of -2. The dependence of U'' at the wall on S is shown in figure 1(b). A positive value is indicative of the existence of an inflexion point. In the absence of slip, the profile is inflexional beyond $S = 2.95$, whereas for $Kn = 0.1$, the profile is inflexional for $S \geq 2.5$. Going by this inviscid argument, a divergent channel might be expected to be more unstable with slip than without, but the difference is too small to predict the direction of the effect at finite Reynolds numbers. We may however estimate that for a profile that is near-inflexional, the divergence could be more important for stability than changes in the boundary conditions. In the next section, we will investigate if the above argument is correct with a non-parallel linear stability analysis.

Non-parallel stability analysis. – We consider small divergence angles and Reynolds numbers are much larger than 1, so streamwise variations in the basic flow are slow. A consistent non-parallel approximation is to retain all terms up to $O(a)$ and $O\left(Re^{-1}\right)$ and to neglect terms of higher order in either of these. As in parallel stability analysis [15], each flow quantity is expressed as the sum of a steady mean and a time-dependent perturbation, such as

$$u = U(y) + \hat{u}(x, y, z, t). \tag{4}$$

Note that, y being the similarity variable, the basic velocity in equation 4 is a function of y alone. Our numerical results for non-similar velocity profiles show that $U = U(y)$ is a fair assumption whenever $\partial U/\partial x$ is smaller than the inverse of the Reynolds number. The dependence on the streamwise coordinate may be expressed as the product of a rapidly varying wave-like part scaled by a relatively slowly varying function (see e.g. [16,17]), and normal modes may be used in the spanwise coordinate z and in time, as

$$[\hat{u}] = \text{Real}\left\{u(x,y)\exp\left[\mathrm{i}\left(\int \alpha(x)\mathrm{d}x + \beta z - \omega t\right)\right]\right\}, \tag{5}$$

such that $\partial u/\partial x \sim O\left(Re^{-1}\right)$. The streamwise and spanwise wavenumbers are α and β respectively and ω is the disturbance frequency. The equations for linear stability under these assumptions are

$$-au + \frac{\partial u}{\partial x} + \mathrm{i}\alpha u - ay\frac{\partial u}{\partial y} + \frac{\partial v}{\partial y} + \mathrm{i}\beta w = 0, \tag{6}$$

$$\begin{aligned} &-\mathrm{i}\omega u + U\left[\frac{\partial u}{\partial x} + (\mathrm{i}\alpha - 2a)\,u\right] + (v - ayu)\,U' \\ &= (2a - \mathrm{i}\alpha)\,p - \frac{\partial p}{\partial x} + ay\frac{\partial p}{\partial y} + \\ &\frac{1}{Re}\left[\frac{\partial^2 u}{\partial y^2} - \left(\alpha^2 + \beta^2\right)u\right], \end{aligned} \tag{7}$$

$$\begin{aligned} &-\mathrm{i}\omega v + U\left[\frac{\partial v}{\partial x} + \mathrm{i}\alpha v\right] + ayU'v = \\ &-\frac{\partial p}{\partial y} + \frac{1}{Re}\left[\frac{\partial^2 v}{\partial y^2} - \left(\alpha^2 + \beta^2\right)v\right], \end{aligned} \tag{8}$$

$$\begin{aligned} &-\mathrm{i}\omega w + U\left[\frac{\partial w}{\partial x} + \mathrm{i}\alpha w\right] = \\ &-\mathrm{i}\beta p + \frac{1}{Re}\left[\frac{\partial^2 w}{\partial y^2} - \left(\alpha^2 + \beta^2\right)w\right]. \end{aligned} \tag{9}$$

The boundary conditions are

$$u \pm Kn\frac{\partial u}{\partial y} = v \mp au = w \pm Kn\frac{\partial w}{\partial y} = 0 \quad \text{at} \quad y = \pm 1, \tag{10}$$

with finite pressure at the walls. In equations (6) to (10), if we set a, and all the streamwise derivative terms to zero, we obtain the Orr-Sommerfeld and Squire equations for parallel flow [15].

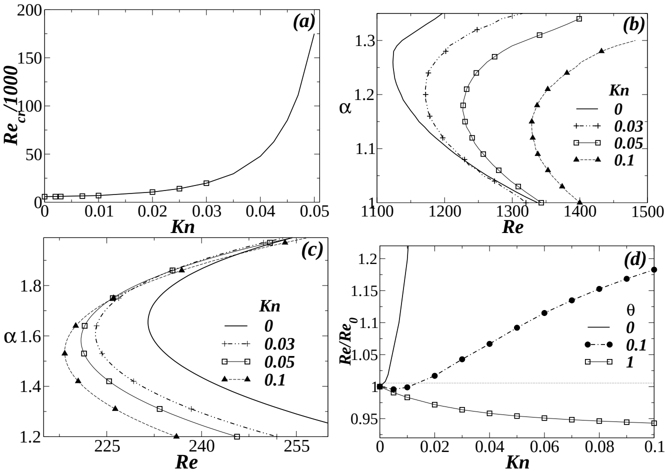

Fig. 3: (a) Variation with velocity slip at the wall of the critical Reynolds number Re_{cr} for linear instability in a plane channel. Line: present study, symbols: [5]. (b) Neutral stability curve for different values of Kn, angle of divergence = 0.1°. (c) Neutral stability curve for different values of Kn, angle of divergence = 1°. (d) Re/Re_0 Vs Kn for different angle of divergence (θ).

We have followed two completely different approaches, described in detail in [17] and [18] respectively, to solve the stability problem of equations (6) to (10). The results agree very well for divergent flows without slip, but the latter method is not applicable for slip flows. In the first method the equations at two neighbouring streamwise locations are rewritten in the form of an eigenvalue problem of larger dimension. This is made possible upon descretising the streamwise derivative, which couples neighbouring streamwise locations to one another, and using the fact that the dimensional frequency remains constant downstream. In the second approach, the lowest-order stability problem correct to $O(Re^{-1/2})$, comprising ordinary differential equations in y is derived. This is solved first as an eigenvalue problem, exactly as one would solve the Orr-Sommerfeld equation. Higher order effects are obtained up to the desired order of accuracy by exploiting the properties of adjoint differential operators. The disturbance amplitude is expressible in terms of an ordinary differential equation in x, whose coefficients contain the lowest-order eigenfunctions. Both methods use Chebyshev collocation spectral discretisation. We always find that the even mode in v is much more unstable than the odd mode. When appropriate, this fact is used to speed up the computations by considering only a half-channel.

While Squire's theorem is not applicable directly for non-parallel flows, it is usually the case that two-dimensional perturbations are the least stable in flows which vary slowly in x. This is true in the case of divergent channels too [19], so only two-dimensional perturbations are presented in this section on linear instability. The two parameters in the problem under consideration are channel divergence and wall slip. For a plane channel

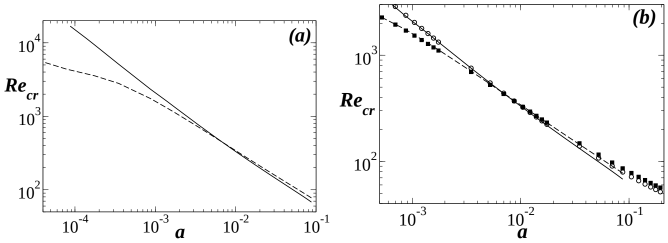

Fig. 4: (a) Variation of the critical Reynolds number, Re_{cr} with wall divergence, solid line: $Kn = 0.1$, dashed line: $Kn = 0$. (b) A portion of figure 4 (a) is magnified, with the corresponding results from the Orr-Sommerfeld equation shown in symbols.

$(\theta = 0)$, the present solutions match well with [5] as seen in figure 3(a). It is seen that the critical Reynolds number increases sharply with increase in the Knudsen number (nearly 175% for a Knudsen number rise of 0.05). For different wall divergence the same variation is given in next two figures as neutral stability curves. The boundaries of neutral stability at various Knudsen number for angles of divergence $\theta = 0.1^\circ$ and 1° are shown in figures 3(b) and 3(c) respectively. At the lower level of divergence, slip is seen to stabilise the flow, but much less than it would in a plane channel, only $\sim 22\%$ for an angle of 0.1°, figure 3(b). At the larger divergence, increasing the Knudsen number has a small destabilising effect only $\sim 10\%$ for an angle of 1°, figure 3(c). The effect of slip and divergence is summarised in the plot of the critical Reynolds number Re_{cr} in figure 3(d). To highlight the result, we plot Re_{cr}/Re_0 Vs Kn, where Re_0 is the critical Reynolds number for the no-slip $(Kn = 0)$ case. As the angle of divergence increases, the effect of slip is progressively reversed, from being hugely stabilising to mildly destabilising.

Figure 4 shows the cross-over in the critical Reynolds number. At a Knudsen number of 0.1, Re_{cr} varies with wall slope approximately as a power law, with an exponent of -0.8. This means that the parameter S at which the flow is neutrally stable increases slowly with the wall slope, roughly as $S \sim a^{0.2}$. It is worth noting that as S increases, the slope of the velocity profile at the wall decreases, so a given Knudsen number corresponds to smaller slip velocities at higher divergences. The results from the Orr-Sommerfeld equation applied to the Jeffery-Hamel profiles are shown in the same figure. It may be concluded that for wall divergences below a degree, flow non-parallelism acts only through the basic profile and the explicit non-parallel terms are negligible. This has been checked to be true for the entire spectrum of eigenvalues for a variety of conditions. Beyond this angle, explicit non-parallel effects are noticeable but not large. Incidentally, this finding is in contrast to what is seen in pipe flows, where the non-parallel terms have a large destabilising effect [17]. At the largest divergences shown, i.e., for $a \sim 0.2$, the flow is mildly separated at the critical Reynolds number. Any firm statements at these angles of divergence would require a non-parallel stability analysis correct to a higher order of accuracy in a and $O\left(Re^{-1}\right)$ than considered here. We only show Orr-Sommerfeld results as a qualitative indicator that nothing special happens when one encounters a mildly separated profile.

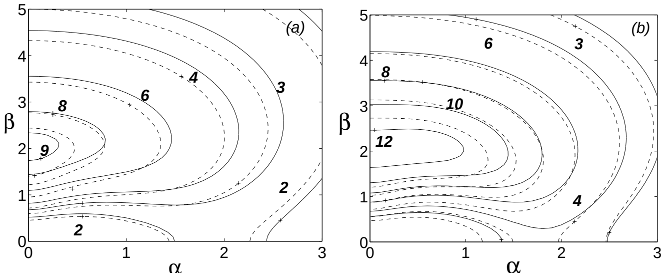

Fig. 5: The contour of G_{max} for $Re = 200$ without slip (solid lines) and at $Kn = 0.1$ (dashed lines) for (a) $a = 0.005$, and (b) $a = 0.02$. At the latter wall divergence, a Reynolds number of 200 is 95% of the critical Re for linear instability.

Transient growth. – In contrast to the least stable linear eigenmode, the maximum transient growth of disturbance kinetic energy is shown here to depend primarily on the Reynolds number of the flow and not on the slope of the walls. The introduction of velocity slip at the walls has a very small effect in the presence of divergence as well, similar to the findings for a plane channel of [5] and [6]. Given the negligible effect of the non-parallel terms on the stability, we use eigenvalues and eigenfunctions from the Orr-Sommerfeld and Squire equations with slip boundary conditions. If $\Lambda = diag\{\omega_1, \omega_2, ...\omega_N\}$ is constructed out of the N least stable eigenvalues of this system, and κ is similarly constructed from the expansion coefficients of the corresponding eigenfunctions, the resulting disturbance kinetic energy, $g(t)$, may be written as [20]

$$g(t) = \frac{\|\kappa(t)\|_E^2}{\|\kappa(0)\|_E^2} = \frac{\|e^{-\mathrm{i}\Lambda t}\kappa(0)\|_E^2}{\|\kappa(0)\|_E^2}. \tag{11}$$

Maximising $g(t)$ for all possible initial conditions $\kappa(0)$, we define

$$G(t) \equiv \max_{\kappa \neq 0} g(t). \tag{12}$$

In a linearly stable situation, the quantity $G(t)$ increases initially, and after attaining a maximum G_{max}, decays to zero as $t \to \infty$. For a given value of Re, α, β and θ, G_{max} is thus the maximum possible factor over which the initial disturbance kinetic energy can grow algebraically. Our computations of $G(t)$ for a plane channel at Reynolds numbers of 1000 and 1500 (appropriately scaled) at different Knudsen numbers are, as mentioned above, in excellent agreement with [6] and [5] respectively.

The contours of constant G_{max} for a range of α and β are plotted in figure 5 for a Reynolds number of 200 and wall slopes of 0.005 and 0.02. The solid line represents the G_{max} at $Re = 200$ for $Kn = 0.0$, whereas the dashed line represents $Kn = 0.1$. It is evident that velocity slip as

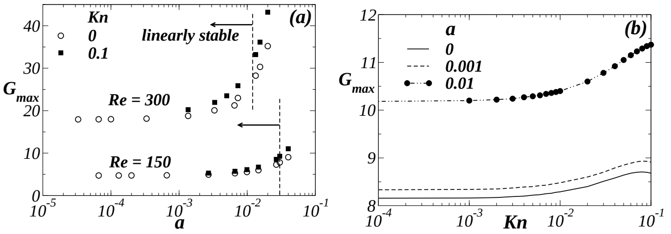

Fig. 6: The maximum transient growth of disturbance kinetic energy at $\alpha = 0$, $\beta = 2.0$ as a function of (a) slope, and (b) Knudsen number. The Reynolds number in (b) is 200. The vertical lines in (a) show the divergence beyond which the flow is linearly unstable at each Reynolds number.

well as channel divergence have only a marginal effect. We now define a Reynolds number $Re_{0.95}$ equal to 95% of the linear instability-critical Reynolds number Re_{cr} for that particular angle of divergence. The algebraic amplification of disturbances obtained at this Reynolds number is close to the maximum possible, since exponential growth will take over at a higher Reynolds number for that angle of divergence. The Reynolds number of 200 at which the contours are shown is about two-fifths of Re_{cr} at $a = 0.005$, while at $a = 0.02$, $Re_{0.95} = 200$. The point to be stressed here is that, even at this "high" Re for $a = 0.02$, the growth is comparable with that of $a = 0.005$. The maximum algebraic growth (i.e., the maximum contour value in figure 5) obtained just before linear instability serves only to amplify the initial perturbation by a factor of ~ 15. This is in contrast to a plane channel, where the factor is about 200 even at one-sixth of Re_{cr} [20]. The results are qualitatively the same over a range of Re and θ.

Throughout the Knudsen number range considered here, the largest transient growth is obtained for streamwise independent disturbances ($\alpha = 0$) of spanwise wavenumber β close to 2, so the remaining results are presented at these wavenumbers. It should be stressed here that the comparisons made are valid irrespective of α and β. Figure 6(a) shows the G_{max} at Reynolds numbers of 150 and 300. The slope at which the flow becomes linearly unstable (to two-dimensional perturbations) is shown by the vertical line in each case. The values of $G_{max}(\alpha = 0, \beta = 2)$ shown beyond this point correspond to the first local maximum. Although this value sharply increases with divergence, it has been checked to be irrelevant in comparison to the exponential growth in the two-dimensional mode. In the linearly stable range, transient growth is (i) small, and (ii) relatively insensitive to wall divergence, unlike the dominant linear mode, which is hugely destabilised. The small destabilising effect of slip on transient growth is summarised in figure 6(b). The combination of wall divergence and wall slip on plane channel is, thus shown to have insignificant algebraic growth. We may conclude that the algebraic growth mechanism is not a major player in diverging channels, whether with or without slip.

In figure 7(a), it is seen that the transient growth obtainable just below Re_{cr} (i.e., $Re_{0.95}$) drops sharply with wall divergence, and is very small even for modest divergence. This result is compared to the maximum transient growth in a plane channel in figure 7(b), solid line. Note that the dashed lines in this figure consist of points from figure 7(a) obtained at various levels of wall divergence, each at its $Re_{0.95}$. At values of wall divergence below 2 degrees or so, the two lines without slip are almost indistinguishable, showing that G_{max} is primarily dependent on the Reynolds number and not on the slope. Scaling arguments at small α show [20] that G_{max} should vary as Re^2. This has been shown to hold true for a variety of flows such as for plane Poiseuille, plane Couette, flow in circular pipes and Blasius boundary layers, with different constants of proportionality. The relationship is seen to hold in the case of divergent flows as well, with $G_{max} \sim f(Kn)Re^2$ where $f(Kn)$ is a weak function of Kn. At higher divergences, where the velocity profile is close to separation at the wall, there is a clear deviation from the power law. This could be of theoretical interest, and merits further investigation.

For the streamwise-independent modes ($\alpha = 0$) our finding that the velocity profile, and thus the level of divergence, do not affect the transient growth, are consistent with earlier analyses on boundary layers [20, 21]. However, at this point we do not have an analytical explanation for the insensitivity to divergence. Note that the Orr-Sommerfeld and Squire equations reduce in this case to

$$\frac{1}{Re}\left(\frac{\partial^4 v}{\partial y^4} - 2\beta^2\frac{\partial^2 v}{\partial y^2} + \beta^4 v\right) = \omega_i\left(\frac{\partial^2 v}{\partial y^2} - \beta^2 v\right), \quad (13)$$

$$\omega_i \eta + \frac{1}{Re}\left(\beta^2\eta - \frac{\partial^2 \eta}{\partial y^2}\right) = -\mathrm{i}\beta U' v. \quad (14)$$

$\hat{\eta}$ is the y component of disturbance vorticity whose amplitude η is defined as in equation (5), and $\omega = \mathrm{i}\omega_i$, since $\omega_r = 0$ for $\alpha = 0$. v is now independent of the velocity profile, but η is not.

For $Kn > 0.1$ we find that the nature, and level of stabilisation is different, but since the slip model is no longer appropriate here, this range is being approached in a different study.

To summarise, it is known that in a plane channel, at Reynolds numbers of about a quarter of Re_{cr}, the levels of transient growth are so high that they can trigger nonlinearities and a transition to turbulence [21]. Recent work shows that a velocity slip at the wall (for small Knudsen numbers) does not much affect transient growth. The implication is that, were the channel to be perfectly plane, one would not expect any big difference in the route to transition, with or without slip. Here, we have investigated how two opposing sources of linear instabilty affect channel flow. We show that for small divergences of the channel wall, the transient algebraic growth is an insignificant player, whether or not the flow is slipping at the wall.

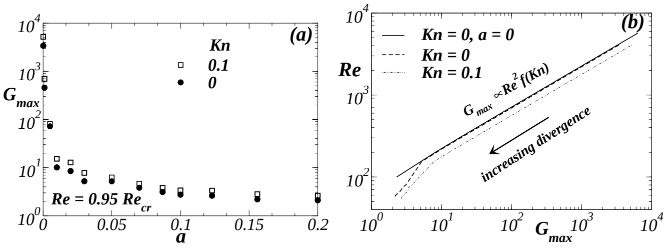

Fig. 7: G_{max} at $\alpha = 0$ and $\beta = 2$, (a) as a function of wall divergence at $Re_{0.95}$. The point at the lowest slope ($a = 10^{-4}$) is obtained at a Reynolds number of $Re_{0.95} = 4282$, while at $a = 0.2$, $Re_{0.95} = 56.6$. (b) as a function of Reynolds number. The solid line is for a plane channel without slip. The long dashes are the quantity shown in (a) plotted now against $Re_{0.95}$. The coincidence of the two lines over most of the range shows that unlike linear instability, the transient growth is not affected by wall slope. The power law behaviour is seen to hold for slip flow as well.

Linear instability on the other hand occurs at Reynolds number two orders of magnitude lower than in a plane channel in spite of the presence of wall slip. We predict that in the presence of divergence and slip, route to chaos is via linear instability for channel and hope to motivate experimental verification of this assertion. Further, we predict that in the presence of local divergence a finite amplitude growth of disturbance will lead to turbulence, irrespective of background noise or slip.

We have considered only Jeffery-Hamel flows, representing long channels with constant divergences, but our results are relevant to channels of arbitrary geometry with local divergences extending to a few channel widths. We have checked that numerical profiles obtained in such channels match closely with Jeffery-Hamel profiles. Restricting ourselves to situations where the inlet flow is relatively quiet, we have not touched upon the role of nonlinearity here, but there are several interesting questions, such as whether a nonlinear self-sustaining mechanism of the general class of [22] would be in operation or whether nonlinear traveling-wave solutions [23,24] will be observed.
